## ABSTRACT

Fruit micromorphology of all 65 native species of the Umbelliferae of the Russian Far East was studied. We described cell arrangement, cell form, fine relief of cell wall (cuticular foldings), epicuticular wax, stomata, crystals. Scanning electron microscope (SEM) also gave information on the inner structure of plant organs. We discuss the diversity of micromorphological characters and their taxonomic value. Some new diagnostic characters for the genera *Kitagawia* (areas with rugulate cuticle), *Ligusticum* and *Magadania* (large convex exocarp cells) were revealed.

**Keywords:** Umbelliferae, taxonomy, identification, SEM

## РЕЗЮМЕ

**Острумова Т.А. Микроморфология плодов зонтичных российского Дальнего Востока.** Изучена микроморфология плодов всех 65 видов зонтичных Российского Дальнего Востока. Мы описываем расположение клеток, их форму, скульптуру кутикулы, эпикутикулярный воск, устьица, кристаллы. С помощью сканирующего электронного микроскопа возможно также изучать внутреннюю структуру органов. Обсуждается разнообразие микроморфологических признаков и их значение для систематики. Для некоторых родов выявлены новые диагностические признаки: участки с морщинистой кутикулой у *Kitagawia*, крупные выпуклые клетки экзокарпа у *Ligusticum* и *Magadania*.

**Ключевые слова:** Umbelliferae, таксономия, определение, сканирующая электронная микроскопия

## INTRODUCTION

Fruit micromorphological studies in the Umbelliferae showed an importance of these characters for taxonomy in the examples of genera *Torilis* (Heywood & Dakshini 1971), *Geocaryum* (Engstrand 1973), *Trinia* (Fedoronchuk 1983), *Eryngium* (Tamamschjan & Pimenov 1987), *Tordylium* (Ai-Eisawi & Jury 1988), *Pastinaca* (Menemen & Jury 2001), *Lichtensteinia* (van Wyk & Tilney 2007), *Rhabdosciadium* (Duran et al. 2010), *Bilacunaria* (Duran et al. 2011), *Diploetaenia* (Duran et al. 2015), *Taenioptetalum* (Ostroumova et al. 2016), *Peucedanum* s. str. (Yildiri & Duman 2017). Studies cover mostly Europe, North and South Africa, Turkey, the Caucasus. There are few publications on Umbelliferae of East Asia, for example, *Acronema* (Wang et al. 2013). We studied fruit micromorphology of almost all the species of Russia and now present an analysis of species of the Russian Far East (Amur, Magadan, Sakhalin regions, Khabarovsk, Primorye and Kamchatka territories and Chukotka Autonomous District). There are 65 native Umbelliferae species in this region.

SEM images provide an opportunity to interpret our observation with an optic stereomicroscope and find new data for plant identification and taxonomic work. For example, the exocarp composed of large convex cells has the appearance of a shiny, grainy surface under the stereomicroscope while the exocarp of small cells is matte and

not grainy. SEM images helped to distinguish between hair types and notice small projections. We used these characters in our identification keys (Pimenov & Ostroumova 2012, Plunkett et al. 2018). Fine details (1–5 µm) can also provide important material for taxonomy (e.g. Fedoronchuk 1983).

## MATERIAL AND METHODS

We studied the fruits of all the native species of the Russian Far East. The fruits were collected during field work, in the living plant collection of MSU Botanical garden, and in some herbaria. Fruit samples are stored in the carpological collection in the Botanical garden of the Lomonosov Moscow State University.

SEM studies of fruits were made with a CamScan S-2 (accelerating voltage 15 kV and working distance 56 mm) at the magnification of 15–3000x. Dry fruits were placed on aluminium stubs and sputter-coated with gold or gold-palladium to a thickness of ca. 25 nm.

In our previous publications we compiled the dictionary for characters and character states for the Umbelliferous fruits (Ostroumova et al. 2010, 2011). Basic points for description of SEM images were published by Barthlot & Ehler (1977) and Barthlot (1981), for the fine relief of the cell wall we used palynological terminology where possible (Hesse et al. 2009).

## Material used for micromorphological investigation

We studies species listed below, from different sources marked as following: BG MSU – fruits harvested on the living plant collection of MSU Botanical garden; CARP – fruits from natural habitats in the carpological collection of MSU Botanical garden; MW, MHA, LE etc. – fruits from herbarium collections. The species of geographic regions outside the Russian Far East are marked with asterisk. Nomenclature is given after Pimenov & Ostromova (2012) and Pimenov (2017).

- Aegopodium alpestre* Ledeb. MW0105723, MW0105704;
- Angelica anomala* Avé-Lall. BG MSU 1982-077;
- Angelica cincta* H. Boissieu BG MSU 1975-363;
- Angelica czernaevia* (Fisch. & C.A. Mey.) Kitag., CARP Primorsky terr. Krivoy Klyuch, 25.09.1960 Pimenov;

## RESULTS AND DISCUSSION

### Pubescence

Hair types, when present, are rather diverse. *Heracleum dissectum* (Fig. 1bc), *H. lanatus*, *Glebinia littoralis* (Fig. 1a), *Phlojodicarpus komarovii* and *P. villosus* have unicellular long, ribbon-like thin-walled hairs. In *Heracleum* and *Glebinia* hair fine relief is smooth or sparsely striate, and in *Phlojodicarpus*, it is rugulate and tuberculate. Hair length in the *Heracleum* and *Phlojodicarpus* species is up to 0.5 mm and in *Glebinia*, up to 1 mm. The ovary in *H. dissectum* is densely pubescent; afterwards the fruit enlarges, some hairs fall away, and the mature fruit became almost glabrous.

In *Anthriscus*, *Osmorhiza*, *Pachyleurum*, *Seseli*, *Torilis*, and in some samples of *Kitagawia komarovii*, hairs are thick-

**Figure 1** Pubescence: a – *Glehnia littoralis*, ribbon-like thin-walled hairs; b, c – *Heracleum dissectum* (b – a base of a fallen hair; c – a flower with densely pubescent ovary); d, e, f – *Anthriscus sylvestris* (d – a thick-walled hair with a multicellular base; e – a glabrous fruit, cell borders inconspicuous, the surface with small dome-shaped bulges; f – a fruit after soaking in acetone, epicuticular wax modified); g – *Osmorrhiza aristata*, a thick-walled hair with a multicellular base; h – *Pachyneurum alpinum*, tiny sharp projections and hairs of variable length; i – *Saponaria divaricata*, a multicellular projection; j, k, l – *Phlojodicarpus villosus* (j – a whole fruit; k – tiny sharp projections and hairs of variable length; l – a hair with tuberculate surface); m, n – *Seseli condensatum* (m – a whole fruit; n – tiny sharp projections and hairs of variable length); o – *Seseli seseloides*, tiny sharp projections and hairs of variable length

walled with rugulate or tuberculate surface. *Phlojodicarpus komarovii* and *P. villosus*, along with ribbon-like hairs, have hard thick-walled ones. *Anthriscus sylvestris* (Fig. 1d,e,f) has either pubescent or glabrous fruits, in Siberia and Far East fruits being usually pubescent. *Anthriscus sylvestris* and *Osmorrhiza aristata* (Fig. 1g) belong to the tribe Scandiceae, they have hairs with multicellular bases, hairs being appressed upward. This hair type is also known in another genera of

Scandiceae, which inhabit the western part of the tribe area, *Myrrhis*, *Myrrhoidea*, and *Scandix*. The tribe Scandiceae is one of the few tribes that has proved to be monophyletic on the basis of molecular data (Spalik et al. 2001, Downie et al. 2010) and micromorphological characters are in accordance with other data sets. *Torilis japonica* of the tribe Caucalideae has appressed hairs on multicellular bases on primary mericarp ribs.

*Angelica genuflexa* and *A. ursina* have sparse and very short (20–30 µm) hairs that are not visible in stereomicroscope at x20; their fruits are usually described as glabrous.

The whole spectrum of hair size from tiny sharp projections to the usual 50–100 (500) µm long hairs are present in *Pachypleurum alpinum* (Fig. 1h), *Phlojodicarpus villosus* (Fig. 1j,k,l), and *Sesel condensatum* (Fig. 1m,n). It is interesting to mention that the geographic areas of these species are broad and include the Arctic. A similar set of hairs and projections are also found on the fruits of *Phlojodicarpus komarovii* (an endemic species of the Russian Far East) and *Sesel seselooides* (Fig. 1o; distributed in the South of the Russian Far East, in Mongolia, China, and the Korean peninsula).

Exozoochoric fruits of *Sanicula* (Fig. 2a,b) and *Torilis* (Fig. 2c,d) are covered with multicellular hooked spines, the spines in *Sanicula* are smooth, and in *Torilis* their surface is densely covered with sharp prickles 10–20 µm long.

The mature fruits of *Saposhnikovia* (Fig. 1i) have multicellular bulges up to 100 µm high, their tops being com-

posed of one to three large cells, 30–70 µm in diam. each, and bases being multicellular of small cells. The top cells have rugulate surface, and the basal cells are striate.

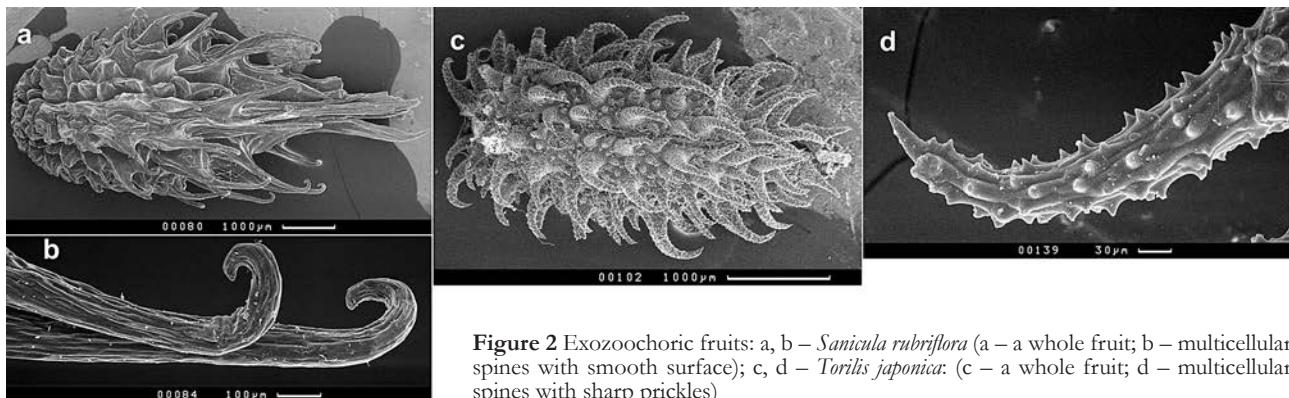

### Characters of exocarp cells

Cell form (Table 1), primary sculpture after Barthlott & Ehler (1977). The ridge of primary rib is rather uniform, it is usually covered with long cells or rows of short cells, or it is longitudinally sulcate. When the fruits are compressed dorsally and have winged marginal ribs, the wing edge is usually covered with isodiametric cells with raised borders and concave periclinal walls (*Angelica*, *Heracleum* (Fig. 3e), *Kitagawia*). The micromorphology of valleculas is more divers and often specific to taxa. We therefore focus primarily on the sculpture of valleculas and rib sides.

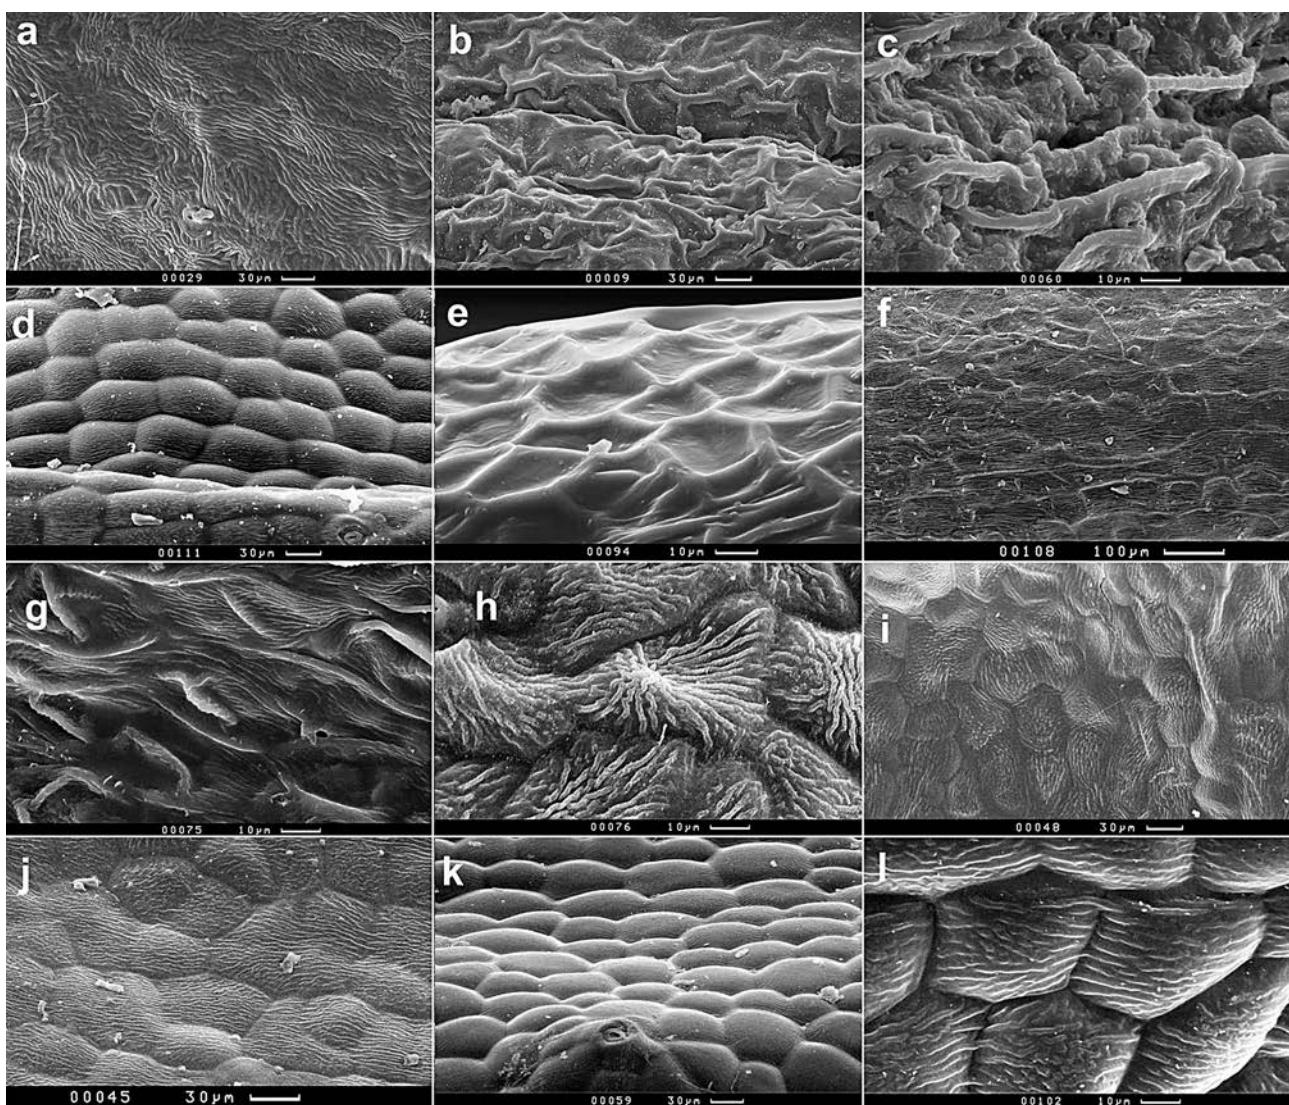

Cell borders are often inconspicuous, and the fruit surface is undulate (*Angelica edulis*, *Osmorhiza aristata*, *Orumbella macounii* (Fig. 3a), *Sesel seselooides*) rugate (*Angelica cincta*, *A. czernaevia*, *A. ursina*, *Bupleurum komarovianum*, *B. longiradiatum*, *Cicuta virosa*, *Kitagawia eryngiifolia*, *K. litoralis*, *Oenanthe*

**Table 1.** Characters of exocarp cells

Species name	Cell size		Cell arrangement		Isodiametric	Cell outlines		Cell borders		Outer periclinal walls

*condensatum*, *S. seseloides*), or obtuse compressed projections (*Kitagavia eryngiifolia*, *K. komarovii*, *K. litoralis*). The foveolate-tuberculate surface most likely occurs when thin outer wall is appressed to dry intracellular content.

Cells are conspicuous all over the fruits in the genera *Halosciastrum*, *Ligusticum* s. str., *Magadania*, *Ostericum*, *Pleurospermum*, *Sanicula*, *Tilingia*, and in *Angelica dahurica*. In some species the cells are visible in some areas only, and conspicuous cell borders are lacking on the rest of fruit surface. We described the cell form when we could find an area of 20 or more cells with conspicuous borders.

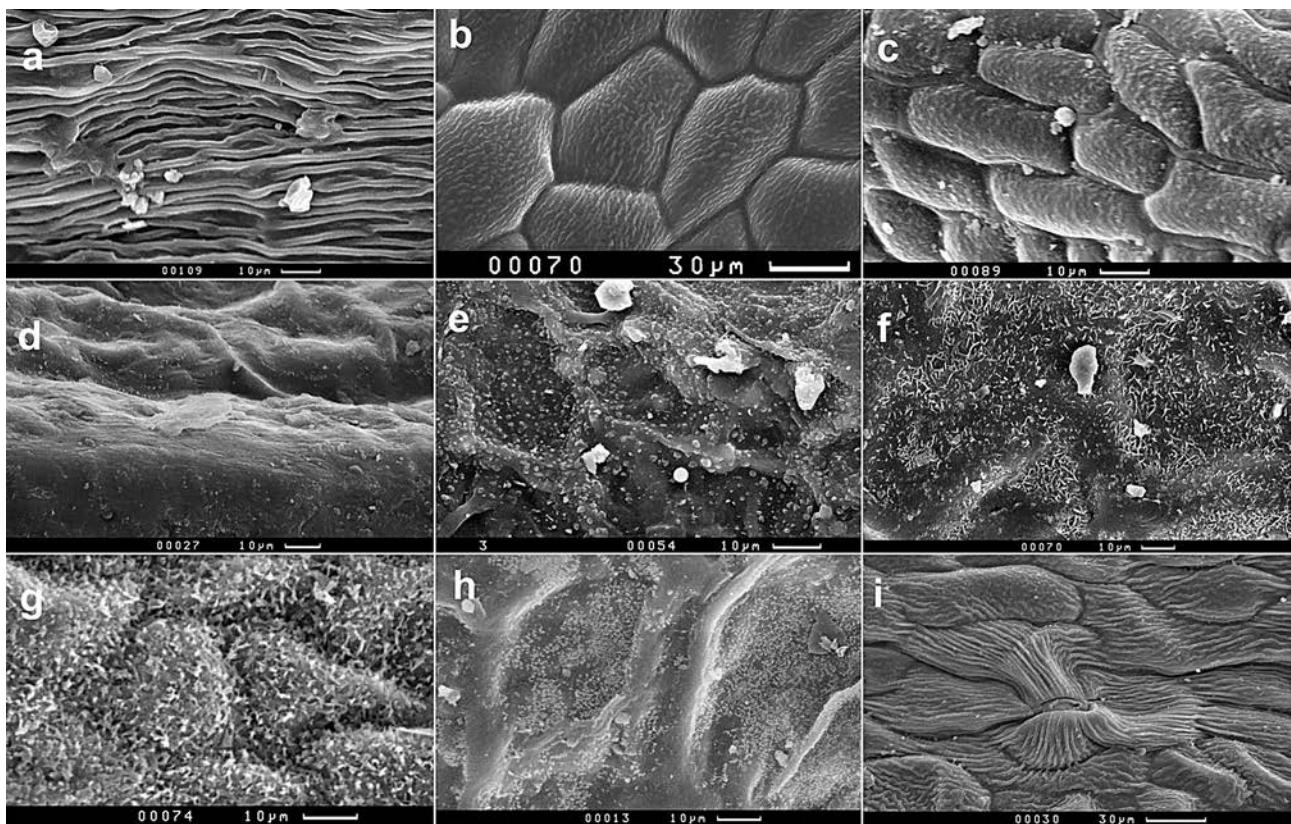

If visible, the cells are arranged in rows (Fig. 3d) or at random (Fig. 3e), and the cell borders are raised (Fig. 3e,f,g) or sunken (Fig. 3d,h–l) and always straight in the species under discussion. The outer periclinal walls are concave (Fig. 3e), flat (Fig. 3f), convex (Fig. 3d,h–l), and with acute (Fig. 1h,k,n,o) or obtuse (Fig. 3g) projection. In *Halosciastrum* (Fig. 3i), *Ligusticum* s. str. (Fig. 3j), *Magadania* (Fig. 3h), *Ostericum* (Fig. 3d), *Pleurospermum* (Fig. 3k), and *Tilingia* (Fig. 3l) exocarp cells are large, >30 µm. Conspicuous, solid, convex exocarp cells are attributed with the above mentioned genera as well as *Aulacospermum*, *Taeniopetalum* and *Hansenia* (incl. *Nothopterygium*) from other regions.

#### Cuticular sculpture and epicuticular wax

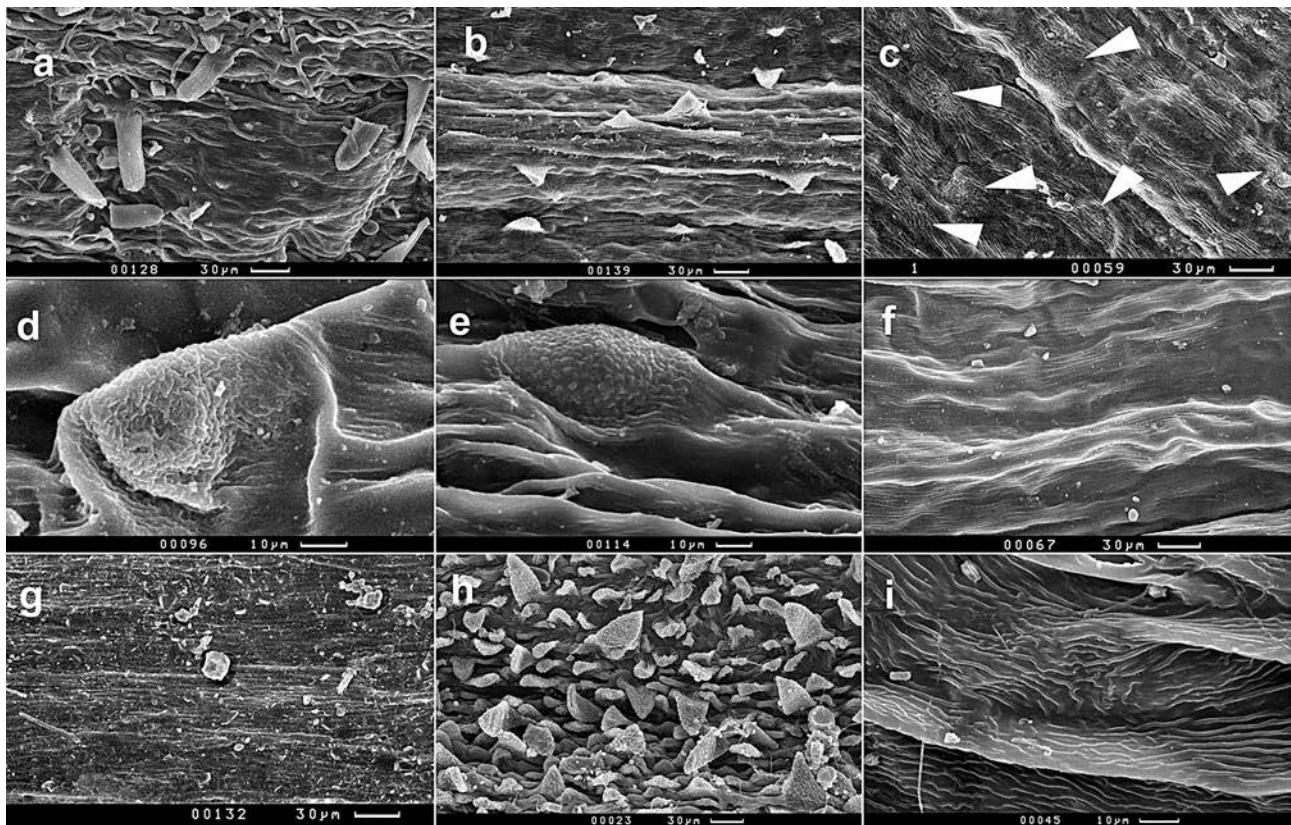

The fine relief of the cell wall (the secondary sculpture, Table 2), is smooth, striate (Fig. 4a), sparingly striate, rugulate (Fig. 4b), sparingly rugulate, tuberculate (Fig. 4c) or striato-knotted (Fig. 3h). The cuticular foldings often correlate with wall shape: flat or concave walls are striate, convex walls are rugulate, and sharp projections are striato-knotted.

The fruits of *Kitagavia* species are mostly glabrous. *K. komarovii* (Fig. 5a,b) is the only species with minute (10 µm) prickles and, occasionally, short hairs up to 50 µm long. These structures are hardly visible under stereomicroscope, and the fruits were described as glabrous. The fruits of other species (including the type species *K. terebinthacea*) are glabrous and have small areas with conspicuous rugulate cuticle, the areas being either flat or slightly convex (Fig. 5c,d,e). For a long time the species were listed in the genus *Peucedanum*, and the genus *Kitagavia* was described in 1986 (Pimenov 1986). Areas with rugulate cuticle are absent in *Peucedanum* s. str. (Fig. 5f,g; Yildiri & Duman 1917) and are an additional diagnostic trait of *Kitagavia*. Recently Pimenov (2017) published five new combinations in *Kitagavia* of the Chinese flora. We studied the fruits of *K. praeruptora* (Fig. 5h) and *K. macilenta* (Fig. 5i). The first species has densely pubescent fruits, the hairs being 30–70 µm long with rugulate and tuberculate cuticle, the second species has the areas with rugulate cuticle.

The cell borders on *Anthriscus sylvestris* (Fig. 1d,e) fruits are indistinct, and there are longitudinal rows

**Figure 4** Cuticular foldings and epicuticular wax: a – *Phlojodicarpus sibiricus*, cuticle striate; b – *Ostericum tenuifolium*, cuticle rugulate; c – *Sanicula rubriflora*, cuticle tuberculate; d – *Sium tenue*, smooth wax layer; e – *Cnidium monnierii*, rough wax layer; f–h – tiny wax platelets (f – *Bupleurum komarovianum*; g – *Bupleurum triradiatum*; h – *Glehnia littoralis*); i – *Magadania victoris*, cuticle around stomata is radially striate

**Figure 5** *Kitagawia* and *Peucedanum*: a, b – *K. komarovii* (a – short hairs and conical projections, b – conical projections only); c – *K. terebinthacea*, areas with rugulate cuticle (arrowheads); d – *K. littoralis*, rugulate cuticle; e – *K. erygijfolia*, rugulate cuticle; f – *P. officinale*, striate cuticle; g – *P. ruthenicum*, striate cuticle; h – *K. praeeruptora*, densely pubescent fruit; i – *K. macilenta*, rugulate cuticle

of semispherical projections. A similar microsculpture was described also in *Geocaryum* (Engstrand 1973) and *Scandix*; all the three genera belong to the tribe Scandiceae. It was noted (e.g. Yurtseva 2007) that single cell sometimes has several projections and that projections can stand either on cell borders or in the middle of a cell. At present we cannot state that one projection corresponds to one cell.

Epicuticular secretions (tertiary sculpture, “wax”, Table 2) are often absent and the cuticular sculpture is clearly visible. A smooth (Fig. 4d) or rough (Fig. 4e) wax layer sometimes masks the cuticula. We observed many irregular particles on some fruit samples, but SEM images do not make it possible to distinguish wax particles from dust or other extraneous matter, so we do not classify such particles as wax. Wax characters of the species studies are shown in Table 2. In many *Bupleurum* species and in *Glebinia*, *Cryptotaenia*, *Spuriopimpinella*, and some species of *Pimpinella* and *Angelica* wax takes the form of tiny scales (Fig. 4f-h). Organic solvents and hot water removes the wax from *Bupleurum* fruits and some other species (Ostromova & Kljuykov 2015), but we could not remove the wax from *Anthriscus sylvestris* mericarps. For example, after soaking the fruits in acetone for 5 days at room temperature, the wax layer changed but was not removed (Fig. 1f). Wax structure

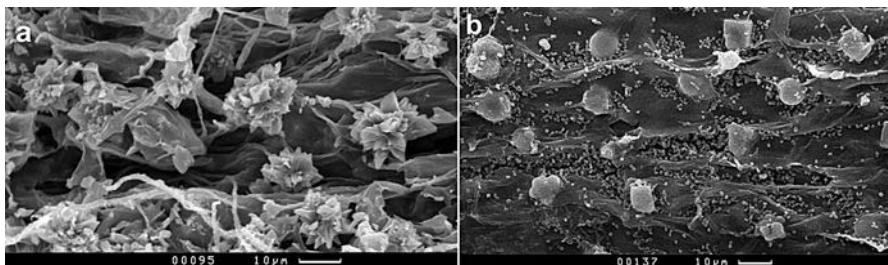

most likely depends on its chemical composition.

Stomata are rare on the fruit surface, in some species we could not find any stomata, while in other species they are solitary (<10 stomata per 1 mm<sup>2</sup>) and usually neither sunken nor raised. In *Pleurospurm uralense* (Fig. 3k) the stomata are located on multicellular tubercles; as to the taxa of other regions, tubercles with stomata were observed in *Aulacostermum*, *Astrantia*, and *Bupleurum*. Sometimes the cuticle around stomata is radially striate: *Heracleum dissectum*, *Magadania victoris* (Fig. 4i), and *Tilingia ajanensis*.

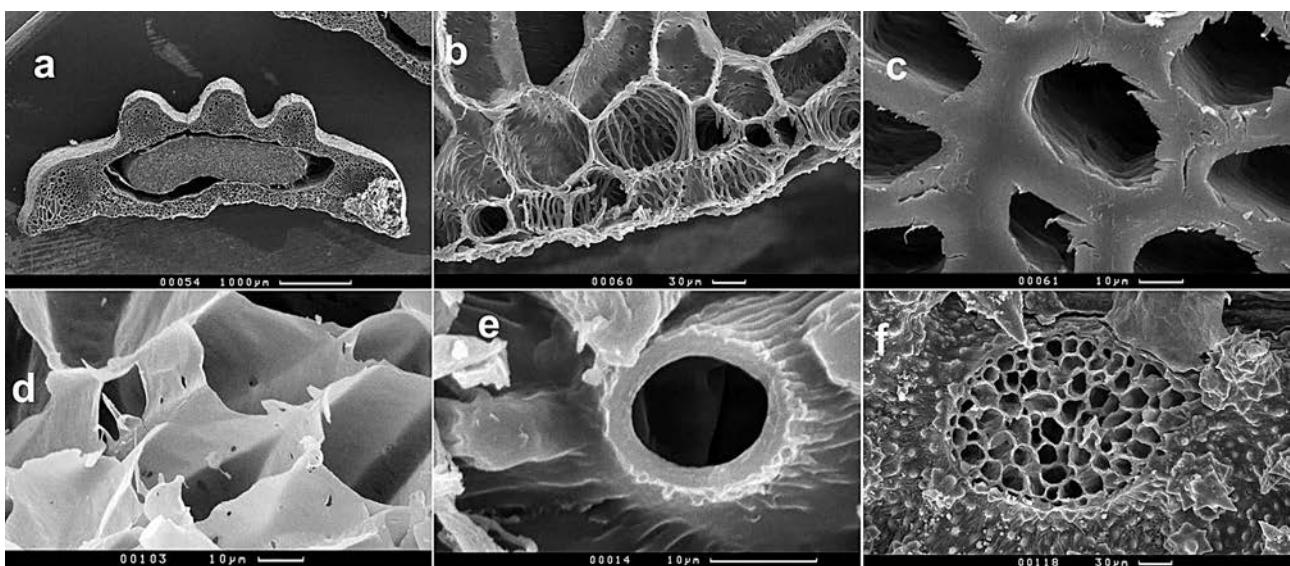

Crystals of calcium oxalate were revealed in the pericarp of several taxa of the Umbelliferae. The taxonomic importance of crystal shape and localization was evident as early as the end of the 19th century (Rompel 1895, Drude 1897-1898). In the subfamily Saniculoideae crystals in the form of druses are located in the mesocarp parenchyma and on the commissural region, this is true for the genus *Sanicula* (Fig. 6a). In the tribes Scandiceae (*Osmorhiza*) and Caucalideae (*Torilis*, Fig. 6b), crystal are restricted to the commissure and their form is rather simple. Commissural crystals are visible to the naked eye as white powder. The most accurate test for crystals is the polarizing microscopy; SEM provides valuable information as well.

SEM also gives information on the inner structure of plant organs. Empty cells with pitted and reticulate secondary walls are quite usual in the dry fruits of Umbelliferae, e.g. *Angelica saxatilis* (Fig. 7d) and *Phlojodicarpus sibiricus* (Fig. 7a,b,c). The outlines of fruit and endosperm transections, localization of secretory ducts, cell size, and the thickness of cell walls (Fig. 7c,e,f) are easily observed.

As with many other plant characters micromorphology does not solve all the taxonomic problems.

**Figure 6** Crystals on the commissural side: a – *Sanicula rubriflora*; b – *Torilis japonica*

**Figure 7** Inner fruit structure: a, b, c – *Phlojodicarpus sibiricus* (a – mericarp transection, b – parenchyma cells with pitted and reticulate walls, c – sclerenchyma); d – *Angelica saxatilis*, parenchyma cells with pitted walls; e – *Seseli seseloides* a thick-walled hair base; f – *Torilis japonica* a base of multicellular spine

In some cases, microsculpture is a valuable source of information, while in other cases (inconspicuous cell borders, no hairs or projections, no peculiar cuticular foldings) we could not find new data for identification and taxonomic revisions.

## ACKNOWLEDGEMENTS

This work is supported by the Russian Foundation for Basic Research (grants No 15-29-02748 and 16-04-00525). SEM studies are performed at the User Facilities Center of M.V. Lomonosov Moscow State University under financial support of Ministry of Education and Science of Russian Federation.
